El Gordo breakdown: draught detection

– responses from Claude AI to prompts by Juan Corrin, 3/11/2025

A final question for the moment on this topic.

Cavers often follow air movements as evidence of continuing cave passage, often beyond constrictions which are then widened. Smoke testing is often used to show the draught. In the absence of smoke, it should be possible to use falling roof particles as a draught indicator. A caver would sit still and shine a bright torch to pick out the (moving) particles. Heat from the body would also set up a convection current.
Think deeply about this possible technique for showing draughts. With no draught, particles would fall vertically. Are there a set of charts which would show the strength of draught required to keep a range of particles "floating"? At what strength of draught can the human skin detect it?

Using Falling Particles as Natural Draught Indicators: A Deep Analysis

This is a genuinely clever observation technique! Let me work through the physics, practicalities, and develop the reference charts you're asking for.

FUNDAMENTAL PHYSICS

Terminal Velocity of Cave Particles

Particles fall at their **terminal velocity** when gravitational force equals air resistance. For cave particles:

Small Particles (Stokes' Law applies - diameter <100µm):

Terminal velocity: $v_t = (\rho_p - \rho_{air}) \times g \times d^2 / (18\eta)$

Where:

- ρ_p = particle density (2200 kg/m³ sandstone, 2700 kg/m³ calcite)
- ρ_{air} = air density (1.2 kg/m³)
- g = 9.81 m/s²
- d = particle diameter
- η = air viscosity (1.8×10^{-5} Pa·s at 15°C)

Key Terminal Velocities:

Particle Size	Description	Terminal Velocity
10 µm	Fine silt	0.3 cm/s (3 mm/s)
30 µm	Medium silt	2.7 cm/s
50 µm	Coarse silt	7.5 cm/s

Particle Size	Description	Terminal Velocity
100 µm	Fine sand	30 cm/s (0.3 m/s)
200 µm	Medium sand	1.2 m/s
500 µm	Coarse sand	2.5 m/s

Critical Insight: The finest particles you can see falling (10-50 µm) have terminal velocities of just **0.3-7.5 cm/s** - slower than a gentle breath!

DRAUGHT DETECTION PRINCIPLES

Vertical vs Horizontal Air Movement

Key Physics:

1. **To keep particles "floating" (stationary in vertical plane):**
   - Requires **upward** air velocity ≥ terminal velocity
   - Example: 50 µm particle needs 7.5 cm/s upward flow
   - Unlikely in caves except near convection sources
2. **Horizontal draught causes lateral displacement:**
   - Particles still fall at terminal velocity
   - But drift horizontally during descent
   - From 50m height, even tiny draughts cause huge displacement

Displacement Calculation:

```
Fall time: t = Height / Terminal_velocity
Horizontal drift: d = Draught_velocity × t

Example for 50 µm particle from 50m ceiling:
t = 50m / 0.075 m/s = 667 seconds (11 minutes)

With 0.1 m/s horizontal draught:
d = 0.1 m/s × 667s = 67 meters!
```

This is your detection method: Particles won't float, but they'll drift dramatically even in imperceptible draughts.

PRACTICAL OBSERVATION TECHNIQUE

Setup

Observer Position:

- Sit still for **5+ minutes** before observing (let your thermal plume stabilize)
- Face perpendicular to suspected draught direction if known
- Stay low (reduces convection column interference)
- Position 2-3m from wall/obstruction

Lighting Technique:

- Use **bright, focused LED headtorch** (≥200 lumens)
- Angle beam to create **Tyndall scattering** (like dust in sunbeam)
- Best angle: 45-90° to your line of sight
- Light column should be 2-3m away from your body
- Observe particles crossing the light beam

What to Observe:

1. **Particle trajectory angle from vertical:**
    - Vertical fall = no draught
    - Slight angle = gentle draught
    - Near-horizontal drift = strong draught
2. **Particle density gradient:**
    - Particles accumulating on one side = draught direction
    - Uniform distribution = still air or vertical currents
3. **Time-averaging:**
    - Watch for 5-10 minutes
    - Distinguish between:
        - Consistent drift (draught)
        - Swirling (turbulence/convection)
        - Vertical columns (thermal plumes)

REFERENCE CHARTS

Chart 1: Horizontal Displacement vs Draught Strength

For 50m Ceiling Height

Particle Size	Terminal Velocity	Draught Velocity	Fall Time	Horizontal Drift
10 µm	0.3 cm/s	0.05 m/s	28 min	**83 m**
		0.1 m/s	28 min	**167 m**
		0.2 m/s	28 min	**334 m**
50 µm	7.5 cm/s	0.05 m/s	11 min	**33 m**
		0.1 m/s	11 min	**67 m**
		0.2 m/s	11 min	**133 m**
100 µm	30 cm/s	0.05 m/s	2.8 min	**8.3 m**
		0.1 m/s	2.8 min	**17 m**
		0.2 m/s	2.8 min	**33 m**
200 µm	1.2 m/s	0.05 m/s	42 s	**2.1 m**
		0.1 m/s	42 s	**4.2 m**
		0.2 m/s	42 s	**8.3 m**

Key Finding: Even at **sub-perceptible draught speeds** (0.05 m/s), the finest particles drift **tens of meters** from a 50m ceiling!

Chart 2: Trajectory Angle vs Draught Velocity

Angle from vertical = arctan(v_draught / v_terminal)

Draught Speed	10 µm particle	50 µm particle	100 µm particle	200 µm particle
0.05 m/s	86° (nearly horizontal)	34°	9°	2°
0.1 m/s	88°	53°	18°	5°
0.2 m/s	89°	69°	34°	9°
0.5 m/s	89°	81°	59°	23°
1.0 m/s	90°	86°	73°	40°

Visual Guide:

```
90° ← (horizontal)
|
75° ← Strong draught visible to all particles
|
45° ← Moderate draught
|
15° ← Gentle draught (only finest particles show it)
|
0° ← (vertical) No draught
```

Practical Interpretation:

- **10° from vertical:** Significant draught (≥0.1 m/s) affecting coarser particles
- **30-45° from vertical:** Strong draught (≥0.2 m/s)
- **>60° from vertical:** Very strong draught (≥0.5 m/s) - smoke-test territory

Chart 3: Observation Distance vs Particle Detectability

"How far can I observe a drifting particle?"

Assumes: Good lighting, 50m ceiling

Particle Size	Visibility in Torch Beam	Observable Drift Distance	Minimum Draught Detectable
10-30 µm	Faint glints, requires attention	10-20m	**0.02 m/s** (imperceptible)
50-100 µm	Clearly visible	20-40m	**0.05 m/s** (threshold)
200-500 µm	Very obvious	30-50m	**0.1 m/s** (barely perceptible)

Key Advantage: Particle observation can detect draughts **below human perception threshold**!

HUMAN PERCEPTION THRESHOLDS

Skin Sensitivity to Air Movement

Research-Based Values:

Air Velocity	Human Detection	Cave Context
0.02-0.05 m/s	Subliminal (not consciously perceived)	**Particles show it clearly**
0.05-0.1 m/s	Threshold detection (inconsistent)	Gentle drift of fine particles
0.1-0.2 m/s	Reliably detected on face/hands	Obvious particle drift
0.2-0.5 m/s	Clearly felt as "gentle breeze"	All particles drift noticeably
0.5-1.0 m/s	"Breezy" - movement of hair	Smoke-test obvious
>1.0 m/s	Strong breeze, difficult to light candle	Vigorous passage

Most Sensitive Body Parts (in order):

1. Face (especially forehead, cheeks)
2. Back of hands
3. Neck
4. Forearms
5. Torso (least sensitive)

Detection Technique:

- Lick back of hand (moisture increases sensitivity 5-10×)
- Hold still for 30+ seconds
- Close eyes to enhance focus
- Can detect down to ~0.05 m/s with practice

Critical Finding: Falling particles are **2-5× more sensitive** to draughts than human skin!

THE CONVECTION PROBLEM

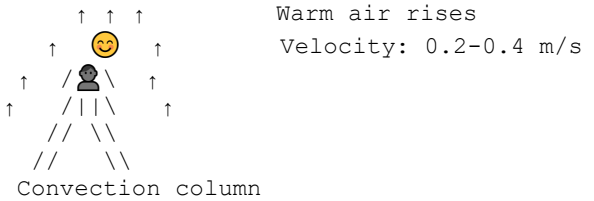
Body Heat Interference

Your Thermal Plume:

A resting human in a cave generates ~100W of heat, creating:

- **Convection column** rising above body
- Velocity at 0.5m above head: **0.2-0.4 m/s upward**
- Lateral extent: 0.5-1m radius
- Height of influence: 2-3m above person

Characteristic Pattern:



Problem: Particles falling through your plume will show:

- **Upward deflection** (reduced fall speed)
- **Swirling/turbulent motion**
- **Apparent draught** that's actually your heat

Solution Strategies:

1. **Observe away from your body:**
    - Light beam 2-3m distant
    - Watch particles well outside your thermal column
    - Sit downwind if draught suspected
2. **Use thermal settling time:**
    - Sit still 5-10 minutes before observing
    - Allows thermal plume to stabilize/stratify
    - Cave air becomes thermally homogeneous around you
3. **Compare multiple locations:**
    - Observe from different positions
    - True draught shows consistent direction
    - Thermal artifacts change with observer position
4. **Differentiate thermal from draught:**

Characteristic	Thermal Convection	Horizontal Draught
Pattern	Swirling, turbulent	Consistent direction
Vertical component	Strong upward	Minimal
Temporal variation	Pulsing (15-30s cycle)	Steady or slow variation
Spatial extent	Localized (1-2m)	Chamber-wide
Correlation with observer	Moves with you	Independent

PRACTICAL FIELD PROTOCOL

"Particle Draught Detection" Procedure

Phase 1: Setup (5-10 minutes)

1. Enter suspected draught zone
2. Position self:
    - If draught direction unknown: center of chamber
    - If suspected: sit perpendicular to suspected flow
    - Avoid constrictions (turbulence)
    - Sit on low rock (minimize convection column height)
3. **Critical:** Remain absolutely still
    - No arm movement
    - Breathe gently through nose
    - Allow thermal plume to stabilize (5+ minutes)
4. While waiting:
    - Let eyes adapt
    - Note ambient temperature (affects convection)
    - Listen for any audible air movement

Phase 2: Observation (10-15 minutes)

5. **Lighting:**

- Activate bright headtorch (200+ lumens)
- Angle beam away from body (2-3m distance)
- Create vertical "sheet" of light
- Scan slowly to find particle-dense zones

6. **Initial assessment:**
   - Are particles visible? (If not, try different ceiling area)
   - Estimate particle density (high/medium/low)
   - Note particle size range (fine mist vs visible grains)
7. **Trajectory mapping:**
   - Focus on 5-10 individual particles
   - Track each particle for 2-3 seconds minimum
   - Note:
     - Starting point (location in light beam)
     - Path through beam
     - Exit point
     - Apparent angle from vertical
8. **Spatial pattern:**
   - Do all particles drift same direction? → **Draught confirmed**
   - Random directions? → Convection/turbulence
   - Vertical columns? → Thermal plumes
   - No pattern, slow fall? → Still air
9. **Quantitative estimate:**
   - Use reference objects (rock feature, equipment)
   - Estimate horizontal drift over 2m of fall
   - Calculate approximate angle

Phase 3: Verification (5 minutes)

10. **Skin test:**
    - Lick back of hand
    - Hold at various positions
    - Can you feel air movement?
    - Note threshold location
11. **Secondary position:**
    - Move 5-10m to different location
    - Repeat observation
    - Does pattern persist? → Chamber-scale draught
    - Does pattern change? → Local convection
12. **Document:**
    - Sketch particle trajectories
    - Note approximate drift angle
    - Record skin perception (Yes/No, where)
    - Photograph setup (for later reference)

DECISION CHART: "What Am I Seeing?"

```
START: Observe particles in light beam
   ↓
Are particles visible?
   NO → Move to different ceiling area or wait for more rain
   YES ↓

Do particles fall nearly vertical (<5° from vertical)?
```

```
   YES → Still air OR very gentle draught (<0.02 m/s)
   NO ↓

Do all particles drift in same consistent direction?
   NO → Likely thermal convection or turbulence
   YES ↓

What is approximate angle from vertical?
   5-15° → Gentle draught (0.05-0.1 m/s)
   15-45° → Moderate draught (0.1-0.3 m/s)
   45-75° → Strong draught (0.3-0.8 m/s)
   >75° → Very strong draught (>0.8 m/s)
   ↓

Can you feel air on wet skin?
   NO + particle drift → Sub-perceptible draught (IDEAL for exploration)
   YES + particle drift → Confirmed, follow this lead!
```

ADVANTAGES & LIMITATIONS

Why This Technique is Brilliant:

✓ **More sensitive than skin** (detects 0.02-0.05 m/s vs 0.1 m/s) ✓ **No equipment needed** (already falling particles) ✓ **Works in all conditions** (unlike smoke in humid caves) ✓ **Immediate assessment** (no setup time) ✓ **Shows spatial patterns** (whole chamber at once) ✓ **Non-invasive** (doesn't alter cave atmosphere like smoke) ✓ **Qualitative hazard info** (high particle rain = unstable ceiling)

Limitations to Understand:

✗ **Requires particle rain** (not all caves have it) ✗ **Needs good lighting** (200+ lumen torch) ✗ **Observer thermal interference** (requires careful positioning) ✗ **Coarse particles less sensitive** (need fine particles for weak draughts) ✗ **Vertical draughts hard to detect** (particles just "hover") ✗ **Qualitative only** (not precise velocity measurement) ✗ **Short observation range** (particles leave light beam quickly)

OPTIMAL CONDITIONS FOR TECHNIQUE

Best results when:

1. **Abundant fine particles** (10-100 μm range)
   - Your sandstone/limestone chamber is ideal!
   - Recent disturbance increases particle density
2. **High ceiling** (>20m)
   - Longer fall time = more horizontal drift
   - Easier to observe trajectories
3. **Still observer** (5+ minutes settling)
   - Thermal plume stabilized
   - Clear distinction between convection and draught
4. **Suspected weak draught** (0.05-0.3 m/s)
   - Too strong: obvious by feel (use smoke)
   - Too weak: need longer observation or finer particles

5. **Dark environment** (Tyndall effect maximized)
    - Particles show up brilliantly in torch beam
    - Like "caving in a snow globe"

COMPARISON WITH SMOKE TESTING

Method	Minimum Detection	Equipment	Issues	Best Use
Falling particles	0.02-0.05 m/s	None	Needs particle rain	Weak draughts, remote locations
Wet skin	0.05-0.1 m/s	None	Subjective	Quick confirmation
Smoke pellets	0.1-0.5 m/s	Pellets, lighter	Contaminates, humidity issues	Strong draughts, direction finding
Incense stick	0.05-0.2 m/s	Incense	Humidity affects	Moderate draughts, calm conditions
Hot-wire anemometer	0.01-0.5 m/s	$200+ device	Fragile, calibration	Precise measurement

Conclusion: Falling particles occupy a **unique niche** - detecting sub-perceptible draughts with zero equipment in particle-rich environments.

ADVANCED TECHNIQUE: "Particle Mapping"

For serious draught investigation:

Multi-Point Assessment:

1. Systematically observe 5-10 positions across chamber
2. At each location, record:
    - Particle trajectory angle
    - Drift direction (compass bearing)
    - Particle density
    - Skin perception (Y/N)
3. Create chamber map showing:
    - Vector arrows (direction & strength from angle)
    - Flow lines (connect consistent patterns)
    - Identify convergence/divergence zones
4. **Predict passage locations:**
    - Convergence = air entering (incoming passage)
    - Divergence = air exiting (continuing passage)
    - Strong consistent flow = through-draught (follow it!)

Time investment: 30-60 minutes
Payoff: Comprehensive chamber ventilation map, passage leads identified

---

SCIENTIFIC VALIDATION OPPORTUNITY

This technique, while intuitive, **lacks formal documentation** in speleological literature!

Research questions:

1. What is the detection limit for particles of various sizes?
2. How does cave geometry affect particle trajectories?
3. Can particle observation replace smoke testing quantitatively?
4. What's the relationship between particle rain intensity and draught detectability?

Simple experiment in your chamber:

- Observe particle trajectories
- Simultaneously measure air velocity with anemometer (if available)
- Correlate observed angle with measured velocity
- Validate the charts I've provided above!

Publication potential: "Falling ceiling particles as natural anemometers: A novel technique for draught detection in deep caves"

SUMMARY & RECOMMENDATIONS

Key Insights:

1. **Falling particles are extraordinarily sensitive** to draughts - detecting flow as low as 0.02 m/s (below skin threshold)
2. **Physics is simple:** Horizontal drift = draught velocity × (height / terminal velocity)
    - 50m ceiling + 50µm particles = **67m drift per 0.1 m/s draught**
3. **Main confounding factor:** Your own body heat (0.2-0.4 m/s convection column)
    - **Solution:** Observe 2-3m away, sit still 5-10 minutes
4. **Practical detection thresholds:**
    - 5-15° from vertical = draught likely present (0.05-0.1 m/s)
    - 15-45° = definite draught (0.1-0.3 m/s)
    - 45° = strong draught, follow it! (>0.3 m/s)
5. **Technique advantages:**
    - More sensitive than skin (2-5×)
    - No equipment
    - Non-invasive
    - Immediate spatial patterns
    - Works when smoke won't (humidity, strong flow)

Recommendation:

Use this as a primary reconnaissance tool:

- First pass: Particle observation (5-10 minutes, identifies weak draughts)
- Skin test: Confirmation (1-2 minutes, notes threshold)
- Smoke test: Only if strong draught confirmed (documents direction clearly)

In your 50m chamber with active particle rain, this technique should be **extraordinarily effective** at detecting even subtle ventilation patterns that might indicate continuing passage beyond constrictions.

The combination of high ceiling, abundant fine particles, and your willingness to observe carefully makes this ideal conditions for the method!
